Geminga is an enigmatic radio-quiet gamma-ray pulsar located at a mere 250 pc distance from Earth. Extended very-high-energy gamma-ray emission around the pulsar has been detected by multiple water Cherenkov detector based instruments. However, the detection of extended TeV gamma-ray emission around the Geminga pulsar has proven challenging for IACTs due to the angular scale exceeding the typical field-of-view. By detailed studies of background estimation techniques and characterising systematic effects, a detection of highly extended TeV gamma-ray emission could be confirmed by the H.E.S.S. IACT array. Building on the previously announced detection, in this contribution we further characterise the emission and apply an electron diffusion model to the combined gamma-ray data from the H.E.S.S. and HAWC experiments, as well as X-ray data from XMM-Newton.

1. Introduction

Geminga (PSR J0633+1746) is a middle-aged pulsar ($\tau_c = 342$ kyr) in close proximity to Earth ($d = 250$ pc), with a spin-down luminosity of $\dot{E} = 3.2 \times 10^{34}$ erg/s, that is radio quiet, yet exhibits pulsed gamma-ray emission. The detection of extended γ -ray emission coincident with the pulsar was first achieved by Milagro [1] and subsequently verified by HAWC [2], yet the angular scale of $\gtrsim 2^\circ$ posed a challenge for Imaging Atmospheric Cherenkov Telescopes (IACTs). The angular scale of the very-high-energy (VHE, $E \gtrsim 100$ GeV) γ -ray emission of $\sim 5.5^\circ$ is considerably larger than that of the associated X-ray pulsar wind nebula (PWN), of $\sim 10'$ [3].

Given that the majority of PWNe that are detected in VHE γ -rays are associated with young, energetic pulsars and that at these later stages the structure of the former PWN has been disrupted, such that particles can leak out into the surrounding interstellar medium (ISM), it was proposed that the γ -ray emission sounding Geminga (and the nearby companion PSR B0656+14) form a distinct class in the evolutionary history of pulsar environments, termed ‘pulsar halos’ (or ‘TeV halos’, whereby the latter is a popular yet ambiguous term) [4, 5]. A key distinguishing feature between PWNe and pulsar halos is the average energy density in electrons responsible for the γ -ray emission via inverse Compton scattering, which for PWNe is higher and for halos lower than that typical of the surrounding ISM [4, 6].

With improving performance and exposure of ground-based particle detector facilities such as HAWC and LHAASO, the γ -ray sky has continued to reveal an increasing number of pulsar halo systems [6]. The morphology of the emission detected with HAWC around the Geminga pulsar indicated that the diffusion coefficient in the vicinity of the pulsar is a factor ~ 100 below the Galactic average expected for the ISM. Several scenarios have been suggested to reconcile the two, such as suppressed diffusion due to turbulence in the vicinity of the pulsar [7].

Accounting for analysis differences between experiments, H.E.S.S. was able to detect the presence of extended γ -ray emission around the Geminga pulsar [8, 9]. To adjust for the large angular size, an observation campaign was conducted in 2019 with telescope pointing offsets of 1.6° (much larger than the usual $\sim 0.7^\circ$), from which a detailed analysis and modelling could be performed. These proceedings provide a summary of the key analysis results and focus on the modelling, where we endeavour to perform a joint fit combining data from HAWC and XMM-Newton to place constraints on the diffusion properties.

2. H.E.S.S. Data Analysis

In [8], the H.E.S.S. Collaboration reported the significant detection of extended gamma-ray emission around the Geminga pulsar, out to at least 3.2° radius. An excess counts sky map constructed using the On-Off background estimation method is shown in figure 1. The 2019 dataset provided 27.2 h exposure with observations obtained at offsets of $\pm 1.6^\circ$ from the location of the Geminga pulsar. Background normalisation was hence performed on data beyond 3.2° (twice the angular pointing offset). This limitation to the sky region meant that the full extent of the emission could not be measured, yet a relative measurement indicating a significant excess above background level was nevertheless found.

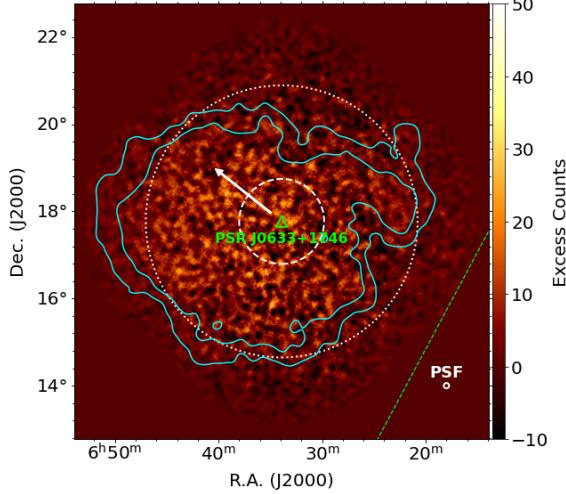

Figure 1: Excess counts sky map of the region around the Geminga pulsar using 2019 data from the H.E.S.S. experiment, analysed with an On-Off background method [8]. The location of the Geminga pulsar is indicated with a green triangle. White dashed and dotted circles indicate the 1° and 3.2° radius regions used for the spectral analysis and the radial profile respectively.

Within the innermost 1° , a significance of $\sim 9 - 10\sigma$ was obtained with different background estimation methods. A spectral analysis was performed to this region, indicated by a white dashed line in figure 1. A power law spectral model was fit to the data, $\frac{dN}{dE} = \phi_0 \left(\frac{E}{E_0}\right)^{-\Gamma}$ with best-fit spectral index $\Gamma = 2.76 \pm 0.22$ and flux normalisation at 1 TeV of $(2.8 \pm 0.7) \times 10^{-12} \text{ cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}$. The spectral results and radial profile are shown together with best-fit models below.

The centroid of the γ -ray emission across the energy range $0.5 \text{ TeV} - 40 \text{ TeV}$ was found to be located at an offset of 0.6° from the pulsar, at R.A. $99.1^\circ \pm 0.1^\circ \pm 0.5^\circ$ and Dec. $17.7^\circ \pm 0.1^\circ \pm 0.5^\circ$, which is nevertheless compatible with the pulsar position within the systematic errors. Evaluating the 68% containment radii in different energy bands, no evidence for statistically significant energy-dependent morphology was found.

3. Diffusion Model

To describe the γ -ray emission, we consider a scenario of electrons diffusing away from the pulsar within a halo region, where the diffusion coefficient has a dependence on energy as $D(E) = D_0(E/E_0)^\delta$ with $\delta \in [0.3, 1]$. The pulsar is considered as a point-like continuous source of electrons, for which we take energy-dependent diffusion and energy losses into account. We solve the diffusive transport equation:

$$\partial_t N(E, \vec{r}, t) - D(E) \Delta N(E, \vec{r}, t) + \partial_E [b(E) N(E, \vec{r}, t)] = Q(E, t) \delta(\vec{r} - \vec{r}_s), \quad (1)$$

where the source term $Q(E, t)$ depends on the energy released by the pulsar and describes the injection of electrons into the pulsar environment:

$$Q(E, t) = Q_0 (1 + t/\tau_0)^{-\frac{(n+1)}{(n-1)}} (E/E_0)^{-\alpha} \exp(-E/E_c), \quad (2)$$

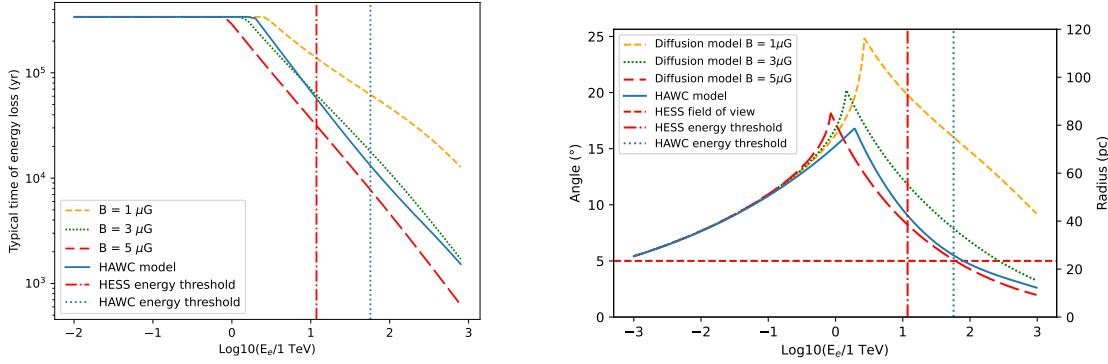

Figure 2: Properties of the electron diffusion model applied. Left: electron energy loss timescale, and Right: electron diffusion radius, both with electron energy and magnetic field strength. The H.E.S.S. energy threshold of ~ 1 TeV applied to this analysis corresponds to an electron energy of $\gtrsim 10$ TeV.

with an initial spin-down timescale τ_0 and braking index n . The solution adopted for the diffusion equation is:

$$N(E, r, T_*) = \int_0^{T_*} dt_0 \frac{b(E_s(E, t_0, T_*))}{b(E)} \frac{1}{(\pi \lambda^2(t_0, T_*, E))^{3/2}} \times \exp\left(-\frac{r^2 + r_s^2(t_0)}{\lambda^2(t_0, T_*, E)}\right) Q(E_s(E, t_0, T_*), t_0), \quad (3)$$

where the subscript $*$ indicates properties of the pulsar at the current time and λ is the diffusion length. Table 1 summarises several parameters of the model, including their fixed and/or scanned values as appropriate.

Figure 2 shows the energy loss time and the diffusion radius. Electrons with energies $\lesssim 1$ TeV have not yet cooled, as the loss timescale is larger than the age of the pulsar. Correspondingly, the peak diffusion radius also occurs at around 1 TeV, above which the expected size due to diffusion decreases with increasing energy. At the energy threshold of H.E.S.S., the diffusion radius is larger than the field of view of the H.E.S.S. telescopes.

4. Modelling Results

To obtain the best-fit model to the HAWC, H.E.S.S. and XMM-Newton data, we performed a parameter scan over variables of the diffusion model as listed in table 1. Five variables ($n, \eta, \alpha, B, \delta$) were scanned over three values, yielding a total of 243 different parameter combinations. The normalisation of the diffusion coefficient was always left as a free parameter of the fit. A global minimisation procedure was found not to converge, as multiple parameter combinations could yield comparably consistent matches to the data. A combination of model parameters was considered a good fit to the data if a p-value of > 0.003 was obtained, a criterion achieved by 53 out of the 243 parameter combinations. The process was repeated with both the cut-off energy of the electron spectrum E_c fixed to 1 PeV and left free to vary.

Figure 3 shows the distribution of fitted E_c for models with p-value > 0.003 ; as expected this depends strongly on the assumed index α of the electron injection spectrum. The best-fit normalisation for the diffusion coefficient is found to be systematically less than the Galactic value

Table 1: Input parameters for the diffusion model, where D_0 is the normalisation at an electron energy $E_0 = 100 \text{ TeV}$. Properties of the pulsar are set to known values where available (e.g. age T_c , distance d , and the luminosity and spin period at the current time, L_* , P_*)

Parameter	Value(s)
Braking index, n	[1.5, 3, 4.5]
Initial period, P_0	15 ms
Transverse velocity, V_T	211 km/s
Electron efficiency, η	[0.01, 0.1, 0.5]
Electron injection index, α	[1.8, 2.0, 2.2]
Electron energy cut-off, E_c	[free, 1 PeV]
Ambient magnetic field, B	[1, 3, 5] μG
Diffusion coefficient normalisation, D_0	free
Diffusion index, δ	[0.3, 0.6, 1]

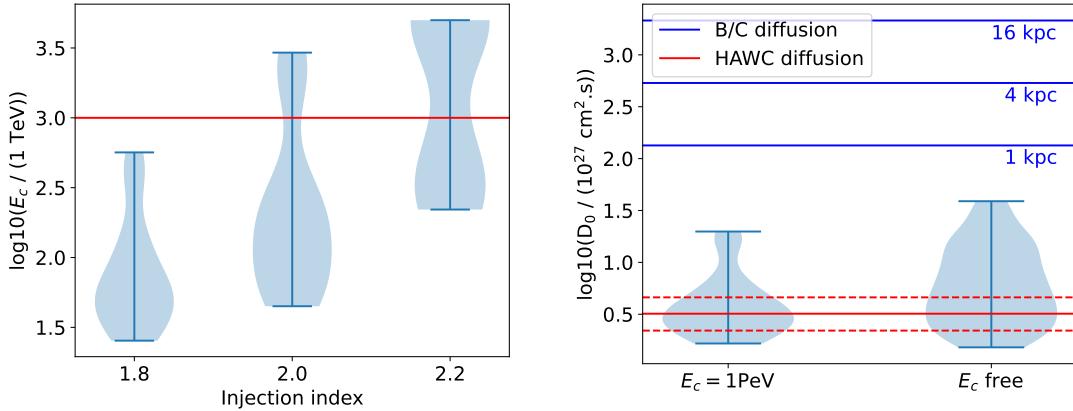

Figure 3: Distribution of best-fit values for all parameter combinations resulting in a p-value < 0.003 . Left: correlation between injection index and cut-off energy when E_c is left free. Right: Best-fit diffusion coefficient in the case of an energy cut-off fixed to 1 PeV and left free to vary.

derived from the cosmic ray B/C ratio (Figure 3). For both cases with $E_c = 1 \text{ PeV}$ and E_c as a free parameter of the fit, the majority of models favour a D_0 value (at an electron energy of 100 TeV) consistent with that obtained in [2].

Figure 4 shows the model curves for all models with a p-value > 0.003 . The highlighted curve represents the model with the highest overall p-value of 0.37, corresponding to the parameter values $n = 4.5$, $\eta = 0.1$, $\alpha = 1.8$, $\delta = 1.0$, $B = 1 \mu\text{G}$ and with fitted parameters $D_0 = 7.6^{+1.5}_{-1.2} \times 10^{27} \text{ cm}^2 \text{s}^{-1}$ and $E_c = 74^{+17}_{-11} \text{ TeV}$. Figure 5 shows a comparison between the best fit and a model curve assuming a scenario in which the diffusion coefficient normalisation adopts a typical galactic average value. This galactic diffusion scenario is defined as $n = 3$, $\eta = 0.5$, $\alpha = 1.8$, $E_c = 74 \text{ TeV}$, $\delta = 0.3$, $B = 3 \mu\text{G}$ [12] and D_0 fixed to B/C diffusion values obtained under different assumptions of the diffusive halo height [13].

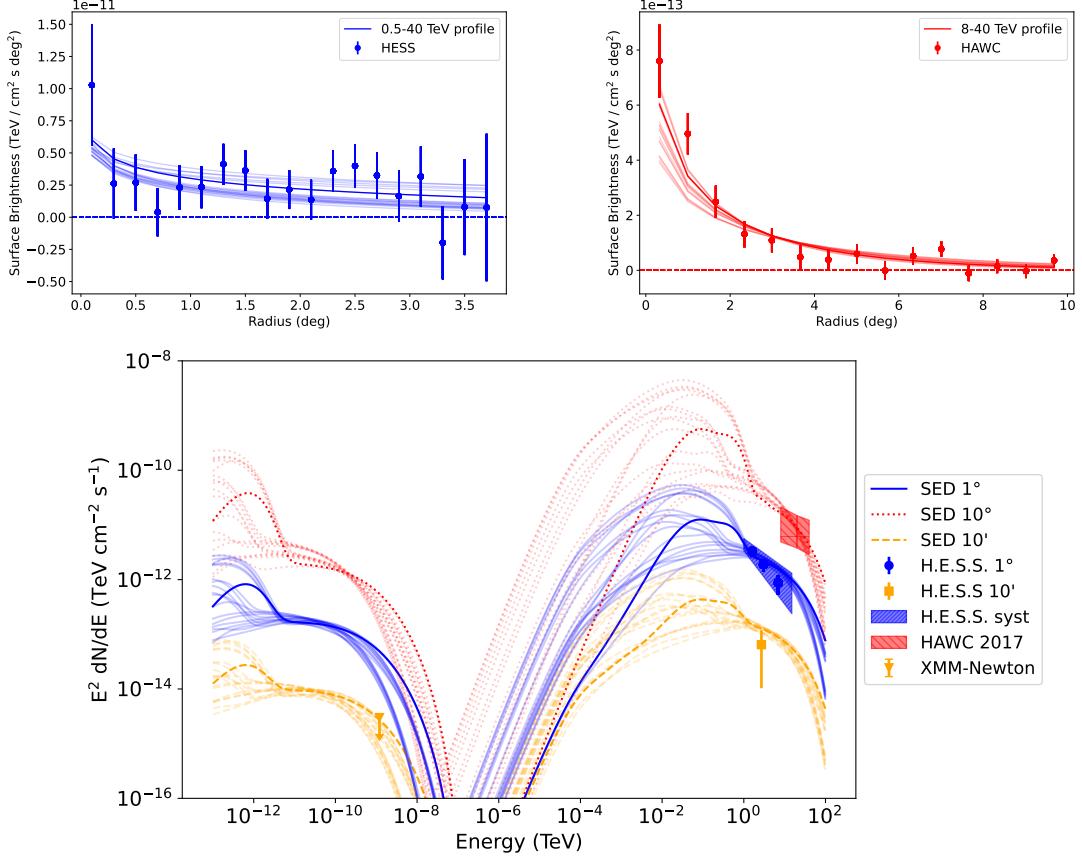

Figure 4: Diffusion model jointly fit to the HAWC, H.E.S.S. and XMM-Newton data. For the two ground-based instruments radial profiles on degree scales are provided. The XMM-Newton upper limit is extracted from a 10' radius region, around the pulsar, from which a corresponding H.E.S.S. flux point is also extracted.

5. Conclusion

With this work, we show that the γ -ray emission detected by H.E.S.S. in the vicinity of the Geminga pulsar [8] is consistent with that measured by [2] in preferring a normalisation of the diffusion coefficient considerably below the galactic average. The detectability of extended γ -ray emission around the Geminga pulsar for both H.E.S.S. and HAWC would have been impossible in a case of a faster diffusion such as that expected in the galactic diffusion scenario. The discrepancy is particularly clear when the model with typical galactic diffusion values is directly compared with data. Based on our investigation of X-ray upper limits within a 10' region surrounding the pulsar, we can draw the conclusion that in a scenario involving a single diffusion zone, and assuming a constant magnetic field spanning the X-ray to γ -ray range, the magnetic field must be less than $1 \mu G$ in the absence of a sub-PeV energy cut-off. To account for a magnetic field of $1 \mu G$, a lower energy cut-off below 75 TeV is necessary.

In conclusion, a scenario comprising galactic-like diffusion and magnetic field properties in the vicinity of Geminga would imply that the halo of electrons would be undetectable in VHE γ -rays by both HAWC and H.E.S.S., and potentially detectable in X-ray. Observational evidence

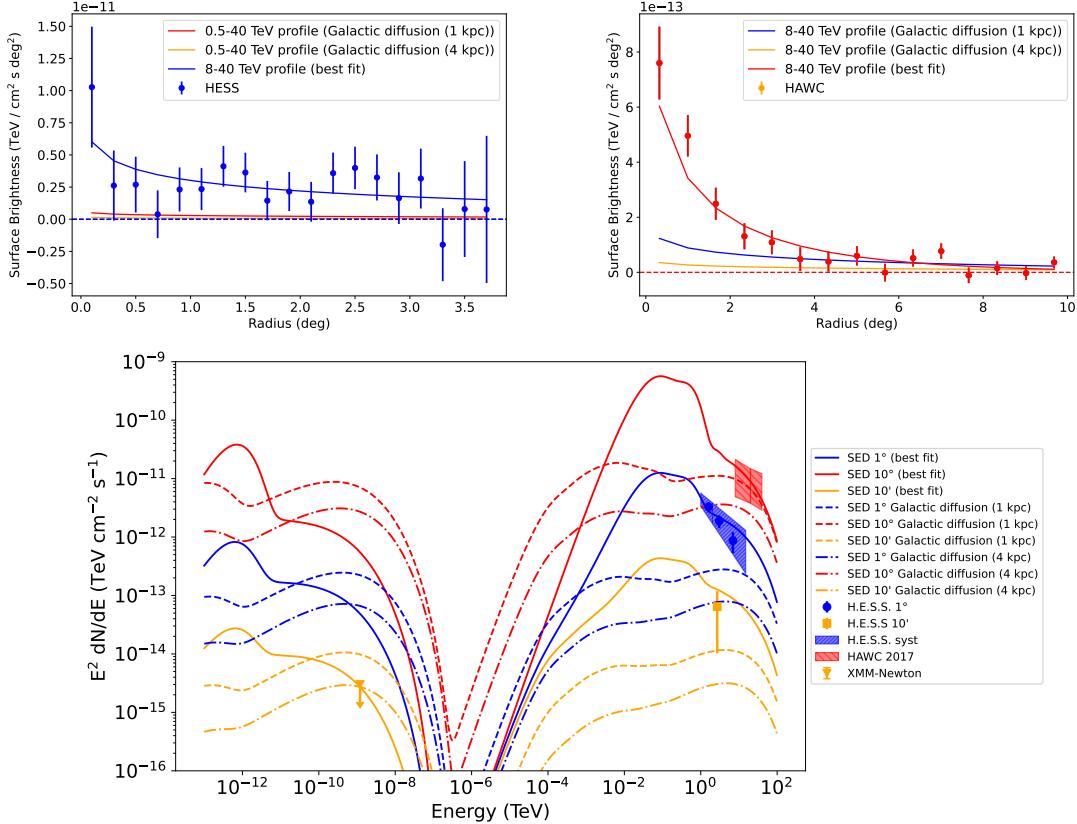

Figure 5: Best fit model jointly fit to the HAWC, H.E.S.S. and XMM-Newton data. For the two ground-based instruments radial profiles on degree scales are provided. The XMM-Newton upper limit is extracted from a 10' radius region, around the pulsar, from which a corresponding H.E.S.S. flux point is also extracted. The SEDs that is obtained for typical galactic diffusion parameters are displayed as well, under the assumption of a diffusive halo height of 1 and 4 kpc.

now indicates that the converse is actually the case, hence the modelling results are consistent with a diffusion coefficient considerably below galactic average values in the vicinity of the Geminga pulsar.
